◊ Introduction ◊

This gem gives a simple algorithm for the incremental construction of the Delaunay triangulation (DT) and the Voronoi diagram (VD) of a set of points in the plane. A triangulation is called *Delaunay* if it satisfies the empty circumcircle property: the circumcircle of a triangle in the triangulation does not contain any input points in its interior. DT is the straight-line dual of the *Voronoi diagram* of a point set, which is a partition of the plane into polygonal cells, one for each point in the set, so that the cell for point p consists of the region of the plane closer to p than to any other input point (Preparata and Shamos 1985,Fortune 1992).

Delaunay triangulations and Voronoi diagrams, which can be constructed from them, are a useful tool for efficiently solving many problems in computational geometry (Preparata and Shamos 1985). DT is optimal in several respects. For example, it maximizes the minimum angle and minimizes the maximum circumcircle over all possible triangulations of the same point set (Fortune 1992). Thus, DT is an important tool for high quality mesh generation for finite elements (Bern and Eppstein 1992). It should be noted, however, that standard DT doesn't allow edges that must appear in the triangulation to be specified in the input. Thus, in order to mesh general polygonal regions the more complicated *constrained* DT should be used (Bern and Eppstein 1992).

The incremental DT algorithm given in this gem was originally presented by Green and Sibson (Green and Sibson 1978), but the implementation is based entirely on the quad-edge data structure and the pseudocode from the excellent paper by Guibas and Stolfi (Guibas and Stolfi 1985). I will briefly describe the data structures and the algorithm, but the reader is referred to Guibas and Stolfi for more details.

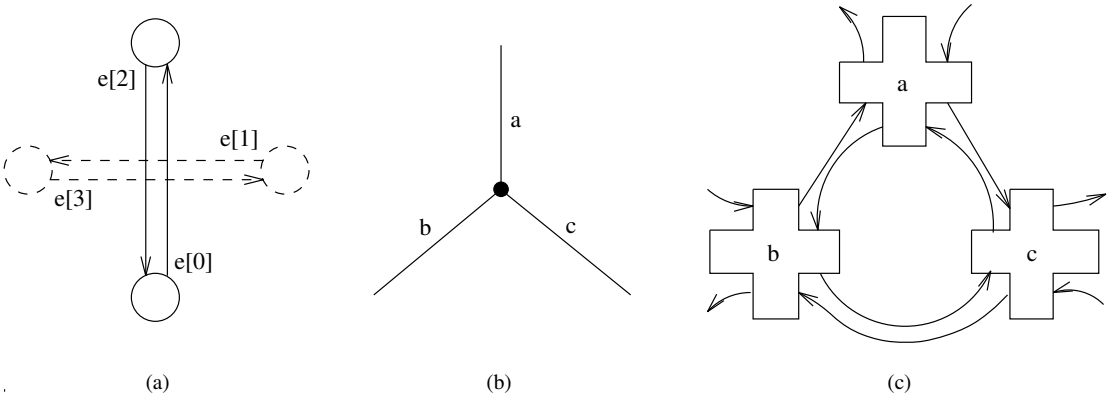

Figure 1. The quad-edge data structure.

♢ The Quad-Edge Data Structure ♢

The quad-edge data structure (Guibas and Stolfi 1985) was designed for representing general subdivisions of orientable manifolds. It is similar to the winged-edge data structure (Baumgart 1975), but it simultaneously represents both the subdivision and its dual. Each quad-edge record groups together four directed edges corresponding to a single undirected edge in the subdivision and to its dual edge (Figure 1a). Each directed edge has two pointers: a `next` pointer to the next counterclockwise edge around its origin, and a `data` pointer to geometrical and other nontopological information (such as the coordinates of its origin.)

Figures 1b and 1c illustrate how three edges incident on the same vertex are represented using the quad-edge data structure: the vertex itself corresponds to the inner cycle of pointers in Figure 1c. The remaining three cycles correspond to the three faces meeting at the vertex.

Aside from a primitive to create an edge (`MakeEdge`), a single topological operator `Splice` is defined that can be used to link disjoint edges together as well as to break two linked edges apart. This operator is its own inverse and together with `MakeEdge` it can be used to construct any subdivision.

♢ The Incremental Algorithm ♢

The incremental DT algorithm starts with a triangle large enough to contain all of the points in the input. Points are added into the triangulation one by one, maintaining the invariant that the triangulation is Delaunay. Figure 2 illustrates the point insertion process. First, the triangle containing the new point p is located (2a). New edges are created to connect p to the vertices of the containing triangle (2b). The old edges of the

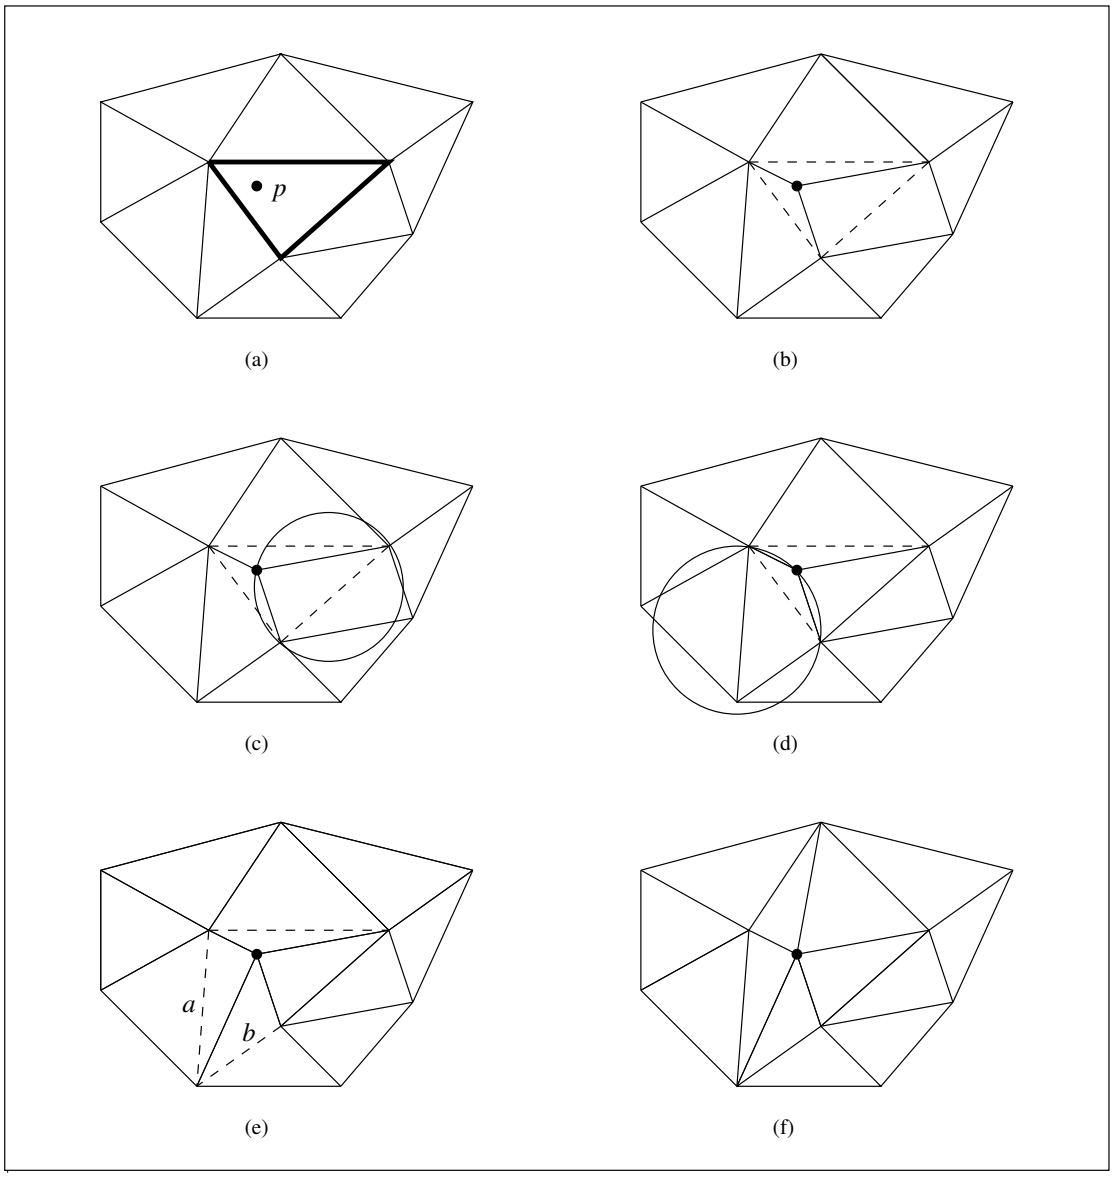

Figure 2. Inserting a point into the triangulation. Dashed lines indicate edges that need to be inspected by the algorithm.

triangle are inspected to verify that they still satisfy the empty circumcircle condition. If the condition is satisfied (2c) the edge remains unchanged. If it is violated (2d) the offending edge is flipped, that is, replaced by the other diagonal of the surrounding quadrilateral. In this case two more edges become candidates for inspection (edges a and b in Figure 2e.) The process continues until no more candidates remain, resulting in the triangulation shown in Figure 2f.

In the worst case the insertion of a point can require $O(n)$ edges to be flipped. However, in practice the average number of edges tested per insertion is small (< 9). Guibas, Knuth, and Sharir have shown that if the insertion order is randomized, the expected time is $O(1)$ per insertion (Guibas et al. 1990).

Locating the containing triangle can be done in an optimal $O(\log n)$ time, but this requires maintaining complicated data structures. Alternatively, the triangle can be located by starting from an arbitrary place in the triangulation and moving in the direction of p until the containing triangle is reached. This requires $O(n)$ time, but if the inserted points are uniformly distributed, the expected number of operations to locate a point is only $O(n^{1/2})$. A simple improvement is to always resume the search from the triangle that was found last: in this way, when the points to be located are near each other, the containing triangles are determined quickly.

Figure 3 shows the DT and the corresponding VD produced by this algorithm from 250 random points in the unit square. Note that because the quad-edge data structure represents both the triangulation and its dual, the topology of the Voronoi diagram is readily available from the DT constructed by the algorithm. To have a complete VD one only needs to compute the circumcenters of all the triangles (i.e., the locations of the Voronoi vertices.)

♢ Robustness ♢

In order to produce a practical implementation of a geometric algorithm, one typically needs to address two problems: geometric degeneracies and numerical errors. For DT, four or more cocircular points in the input constitute a geometric degeneracy and the resulting DT is not unique. In such a case this algorithm will produce one of the possible triangulations as output.

Dealing with numerical errors is more difficult. Various applications in which the need for DT or VD arises differ in the nature of their input and in their output accuracy requirements. Therefore, it is very difficult to come up with a single efficient solution to the problem. Karasick, Lieber and Nackman suggest a solution that uses rational arithmetic as well as survey other approaches (Karasick et al. 1991).

In this implementation all the computations are performed using standard floating point arithmetic. Epsilon tolerances are used to determine whether two point coincide and whether a point falls on an edge. No other special measures to ensure robust-

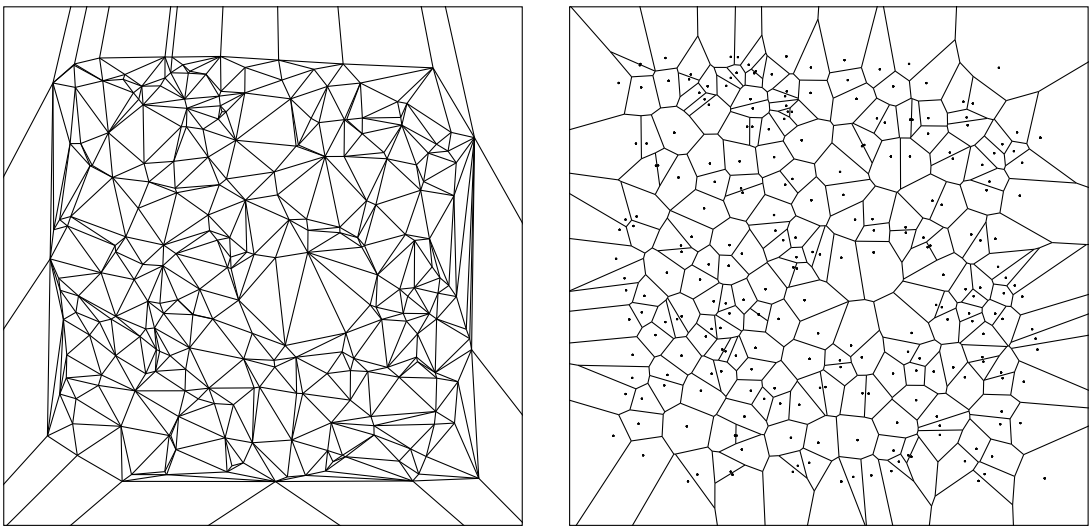

Figure 3. The DT (left) and the VD (right) of 250 random points uniformly distributed in the unit square.

ness were taken. Nevertheless, largely because of the simplicity of the algorithm, the implementation has proven to be very robust.

♢ C++ Code ♢

The code listed below is the C++ implementation of the quad-edge data structure and the incremental Delaunay triangulation algorithm. In addition, the disk that comes with this book contains code for 2D vectors, points, and lines and a test program. This program constructs and displays a triangulation, allowing the user to add more points into the triangulation interactively by clicking a mouse button at the place of insertion. The code should compile and execute on SGI graphics workstations.
